Summary

Background Human papillomavirus (HPV) vaccination programmes were first implemented in several countries worldwide in 2007. We did a systematic review and meta-analysis to assess the population-level consequences and herd effects after female HPV vaccination programmes, to verify whether or not the high efficacy reported in randomised controlled clinical trials are materialising in real-world situations.

Methods We searched the Medline and Embase databases (between Jan 1, 2007 and Feb 28, 2014) and conference abstracts for time-trend studies that analysed changes, between the pre-vaccination and post-vaccination periods, in the incidence or prevalence of at least one HPV-related endpoint: HPV infection, anogenital warts, and high-grade cervical lesions. We used random-effects models to derive pooled relative risk (RR) estimates. We stratified all analyses by age and sex. We did subgroup analyses by comparing studies according to vaccine type, vaccination coverage, and years since implementation of the vaccination programme. We assessed heterogeneity across studies using I^2 and χ^2 statistics and we did trends analysis to examine the dose-response association between HPV vaccination coverage and each study effect measure.

Findings We identified 20 eligible studies, which were all undertaken in nine high-income countries and represent more than 140 million person-years of follow-up. In countries with female vaccination coverage of at least 50%, HPV type 16 and 18 infections decreased significantly between the pre-vaccination and post-vaccination periods by 68% (RR 0.32, 95% CI 0.19–0.52) and anogenital warts decreased significantly by 61% (0.39, 0.22–0.71) in girls 13–19 years of age. Significant reductions were also recorded in HPV types 31, 33, and 45 in this age group of girls (RR 0.72, 95% CI 0.54–0.96), which suggests cross-protection. Additionally, significant reductions in anogenital warts were also reported in boys younger than 20 years of age (0.66 [95% CI 0.47–0.91]) and in women 20–39 years of age (0.68 [95% CI 0.51–0.89]), which suggests herd effects. In countries with female vaccination coverage lower than 50%, significant reductions in HPV types 16 and 18 infection (RR 0.50, 95% CI 0.34–0.74) and in anogenital warts (0.86 [95% CI 0.79–0.94]) occurred in girls younger than 20 years of age, with no indication of cross-protection or herd effects.

Interpretation Our results are promising for the long-term population-level effects of HPV vaccination programmes. However, continued monitoring is essential to identify any signals of potential waning efficacy or type-replacement.

Funding The Canadian Institutes of Health Research.

Introduction

Since 2007, 52 out of 195 countries worldwide have implemented human papillomavirus (HPV) vaccination programmes, including 41% of high-income countries and 15% of low-income and middle-income countries.^{1–4} The population-level effect of HPV vaccination programmes is expected to vary substantially between these countries, depending on the vaccine used, implementation strategies, and vaccination coverage achieved. Two HPV vaccines are currently available worldwide: the bivalent vaccine, which targets HPV types 16 and 18 (which are associated with 70–80% of cervical cancers globally⁵), and the quadrivalent vaccine, which also targets HPV types 6 and 11 (associated with 85–95% of

cases of anogenital warts⁶). Most high-income countries are using the quadrivalent vaccine, whereas a mixed picture exists for low-income and middle-income countries.^{2,7} Although all HPV vaccination programmes target pre-adolescent girls (and might also include catch-up programmes for older girls and women), a few countries, such as the USA and Australia, have recently begun to include boys.^{8,9} Finally, in high-income countries, vaccination coverage in the younger cohorts of girls ranges from nearly 90% to less than 50%, mostly depending on whether the countries have school-based or non-school-based vaccination programmes.¹⁰

Large international randomised controlled clinical trials have shown both HPV vaccines to be safe and well

tolerated, highly efficacious against vaccine-type persistent HPV infection and precancerous cervical lesions in women (vaccine efficacy 93–100%),^{11,12} and to provide some degree of cross-protection against three non-vaccine types (HPV types 31, 33, and 45),^{12–14} which are associated with 10–15% of cervical cancers worldwide.¹⁵ Existing evidence from clinical trials also suggests that cross-protective vaccine efficacy estimates against infections and lesions associated with HPV types 31, 33, and 45 are higher for the bivalent vaccine than for the quadrivalent vaccine.¹⁶ Following clinical trials, mathematical models have been used to predict the long-term population-level effectiveness and cost-effectiveness of vaccination programmes delivered in different settings. Modelling studies have consistently predicted that the overall burden of HPV-related diseases in women will decrease substantially in the next few decades through vaccination, and that vaccination of girls against HPV is highly cost effective in most countries.^{17–19} Despite consistency in model predictions of the direct effects of HPV vaccination in vaccinated girls, uncertainty remains about the potential population-level effects of cross-protection and herd protection (eg, the indirect consequences of vaccinating girls on HPV in unvaccinated boys, men, and adult women), and the vaccination coverage necessary to achieve substantial herd effects.^{20–24} This information is crucial to help guide vaccine choices and inform decisions about vaccination of boys and men.

Now that more than 7 years have elapsed since the implementation of the first HPV vaccination programmes in 2007 (appendix pp 2–4), it is timely to verify whether or not the promising results from clinical trials and model projections are materialising at the population level. An increasing number of post-vaccination surveillance studies have recently been published using several intermediate endpoints (eg, HPV infection, anogenital warts, and precancerous cervical lesions). The aim of this systematic review and meta-analysis is to summarise existing evidence about the population-level effect of HPV vaccination, as measured in time-trend studies in girls and young women targeted for vaccination, and in boys, men, and older women. We focused on three HPV-related endpoints: HPV infection, anogenital warts, and high-grade cervical lesions.

Methods

Search strategy and selection criteria

We systematically reviewed the global literature and report it in accordance with the PRISMA guidelines.²⁵ Studies were eligible for inclusion if they fulfilled the following criteria: they provided data about at least one endpoint of HPV infection, anogenital warts, histopathologically confirmed high-grade cervical lesions (cervical intraepithelial neoplasia [CIN] 2 or worse); if they assessed the population-level effect by comparing the frequency (prevalence or incidence) of the endpoint between the pre-vaccination and post-vaccination periods

(ie, time-trend studies); and if data from the pre-vaccination and post-vaccination periods were collected from the same population sources with use of the same recruitment methods.

We excluded studies with the following characteristics because they did not measure population-level effect: if HPV vaccination was administered as part of an individual-based randomised trial, or HPV vaccination effect was assessed by comparing the frequency of the endpoint between vaccinated and unvaccinated people during the post-vaccination period.

Our search strategy had three stages. First, we searched the Medline and Embase databases between Jan 1, 2007, and Feb 28, 2014, with a combination of the following Medical Subject Heading (MeSH) terms, title, or abstract words, with no restriction on the language of publication: ("papillomavirus vaccine", "papillomavirus vaccination", "HPV vaccine", or "HPV vaccination") and ("program evaluation", "population surveillance", "sentinel surveillance", "incidence", or "prevalence"), and ("papillomavirus infection", "condylomata acuminata", "anogenital warts", "cervical intraepithelial neoplasia", "cervical dysplasia", "uterine cervical neoplasm", or "HPV related diseases"). We identified eligible studies by reviewing titles and abstracts, and we also searched the reference lists of eligible articles. Second, we reviewed the abstracts of recent major conferences on HPV (the European Research Organisation on Genital Infection and Neoplasia [EUROGIN] Congress 2013 and the International Papillomavirus Conference 2012) to identify additional unpublished studies. Third, MD and MB contacted the authors of conference abstracts to obtain unpublished data. MD and EB independently assessed the eligibility of all studies. Additionally, DM independently assessed the eligibility of studies of HPV infection. If more than one publication from the same data source and research team was available, we kept the publication that presented the most recent data.

Data extraction and quality assessment

Our primary outcomes were the relative risks (RR) comparing the pre-vaccination and post-vaccination periods for: the prevalence of HPV infection for four HPV type subgroups (high-oncogenic risk vaccine types [HPV16 and HPV18], three types with the greatest evidence of cross-protective efficacy [HPV31, HPV33, and HPV45],¹⁶ the five potentially cross-protective types [HPV31, HPV33, HPV45, HPV52, and HPV58],¹⁶ and all high-oncogenic risk non-vaccine types [all high-risk HPV types except for HPV16 and HPV18]); the frequency (prevalence or incidence) of anogenital wart diagnosis; and the frequency (prevalence or incidence) of high-grade cervical lesions. Two authors (MD and EB) independently extracted the study characteristics and outcomes using a standardised form. MD and MB contacted authors to request supplementary extractions to standardise data stratifications between studies for comparison and

pooling (eg, same age and HPV type groupings). We also collected information about the vaccination programme characteristics and vaccination coverage of the country or region of each study (appendix pp 2–4). For the HPV prevalence studies, we collected age-specific vaccination coverage directly from each study, since vaccination status was available for all study participants. Finally, the authors of each article validated the data from their study.

Before contacting the study investigators, MD, AM, PLM, and MB assessed whether or not the studies had sufficient methodological quality to be included in the meta-analysis. The quality of the studies (potential for bias and confounding, and external validity) was assessed independently from the investigators of the original studies. Potential for bias and confounding within studies were assessed by review of the participant selection or recruitment procedures, endpoint definitions, algorithms used to identify cases, and potential confounders considered in the statistical analyses (appendix pp 5–9).

Data analysis

Because mostly girls (<20 years of age) were vaccinated in the study populations, we decided a priori to stratify all our analyses by sex and age. Furthermore, because only

the quadrivalent vaccine includes HPV types 6 and 11 (which are responsible for roughly 90% of cases of anogenital warts⁶), we decided a priori to stratify our analyses for anogenital warts by the type of vaccine.

To ensure comparability of the study results included in the meta-analysis, we first defined pre-vaccination and post-vaccination periods for all studies (appendix pp 10–11). Second, for comparability, we used prevalence or incidence rate ratios as the measure of effect for all HPV-related endpoints. For HPV infection, most studies presented RR (crude and/or adjusted prevalence ratios) and 95% CIs. When available, we included adjusted RR in the meta-analysis. When only crude HPV prevalence over time was available, we calculated prevalence ratios by dividing the post-vaccination and pre-vaccination prevalence and estimated the 95% CI (CI approximation for prevalence ratios²⁶). For anogenital warts and precancerous lesions, all studies presented annual frequency (prevalence or incidence) over time. We estimated pre-vaccination frequency by aggregating the data for up to 3 years before vaccination, and calculated RR by dividing each post-vaccination year by the pre-vaccination estimate.

We derived summary estimates of the effect of HPV vaccination for each endpoint by using random-effects

OR=odds ratio. HPV=human papillomavirus. RR=relative risk (post-vaccination prevalence or incidence/pre-vaccination prevalence or incidence). CIN=cervical intraepithelial neoplasia. *Data sources are regarded as population based when the study population includes the entire population of a given country or region; health provider or insurance based when the study population consists of a subgroup of the total population participating in a specific health programme or insurance plan; and clinic based when the study population comprises a finite number of clinics or hospital's clients. †For studies of HPV infection, the pre-vaccination and post-vaccination periods were already established in the original publications (except for Kavanagh et al³¹). For studies of anogenital warts and cervical lesions, the pre-vaccination and post-vaccination periods were established for the purpose of this systematic review as described in appendix pp 10–11. ‡The sample size is restricted to the age groups used in the review. For studies of HPV infection, the pre-vaccination and post-vaccination sample sizes were already established in the original studies. For studies of anogenital warts and cervical lesions, the pre-vaccination sample size corresponds to the cumulative number of person-years up to 3 years pre-vaccination, including the year of the introduction of HPV vaccination. The post-vaccination sample size corresponds to the cumulative number of person-years from 1–4 years after the introduction of vaccination, depending on the data available in each study. §For HPV infection, the investigators recalculated the RR of prevalence using the original data from their specific studies. For anogenital warts and precancerous lesions, we estimated pre-vaccination frequency by aggregating the data for up to three years before vaccination, and calculated RR by dividing each post-vaccination year by the pre-vaccination estimate. ¶13 high-risk HPV types were presented in the original publications, whereas the 18 high-risk HPV types available were used for the purposes of this meta-analysis. ||Data from this study are restricted to the Victorian registry data. Supplementary data from the Australian Institute of Health and Welfare 2013 report⁴⁵ were provided by Brotherton (JML Brotherton, National HPV Vaccination Program Register, Victorian Cytology Service, East Melbourne, Melbourne, VIC, Australia, personal communication). Since the report covers all regions of Australia, we used it as our main data source for the review.

Table: Characteristics of the studies included in the systematic review and meta-analysis

or 30–39 years), years since the vaccination programme was implemented (1, 2, 3, or 4 years), source of study data (population based, health provider/insurance based, or clinic based), and by whether or not the impact measure was adjusted (yes or no). We examined heterogeneity across studies using I^2 and χ^2 statistics.²⁸ I^2 values less than 50% represent low heterogeneity, between 50–75% substantial heterogeneity, and more than 75% high heterogeneity.²⁹ The p value associated with the χ^2 statistic represents the statistical significance of heterogeneity. Finally, we analysed the dose–response association between HPV vaccination coverage (independent variable) and the log-RR of each study (dependent variable) by fitting a linear regression, weighted by the inverse variances of the log-RR.³⁰ We used Review Manager 5.2 and SAS 9.4 for all analyses.

Role of the funding source

and had final responsibility for the decision to submit for publication.

Results

In our searches we identified 661 articles and 29 conference abstracts, of which 20 records met the inclusion criteria (seven on HPV infection,^{31–37} 11 on anogenital warts,^{38–48} and two on high-grade cervical lesions;^{49,50} figure 1, table). The studies were done in nine high-income countries (the USA, Australia, England, Scotland, New Zealand, Sweden, Denmark, Canada, and Germany) and assessed the population-level consequences of vaccination in 16600 women for HPV infection, more than 125 million person-years of follow-up for anogenital warts, and 15 million female-years of follow-up for high-grade cervical lesions (table). The vaccine used, vaccination strategy, delivery, and vaccination coverage varied substantially (table and appendix pp 2–4). All studies had sufficient methodological quality to be included in the meta-analysis (appendix pp 5–9). However, because two studies analysed the entire Danish population during

Figure 2: Changes in the prevalence of HPV infections between the prevaccination and postvaccination periods in (A) girls aged 13–19 years and (B) women aged 20–24 years, ranked by age-specific vaccination coverage (≥ 1 dose) reported in studies

RR=relative risk. HPV=human papillomavirus. NA=not available. p values for trends were obtained by fitting a linear regression between the log RR and the age-specific coverage of each study, weighted by the inverse variances of the log RR. The minimum age of participants varied between studies (see table 1). *Age-specific proportion of female participants, included in the analysis of each study, who received at least one dose of the HPV vaccine. †Data not available for girls aged 13–19 years in Kavanagh et al, and for women aged 20–24 years in Cummings et al. ‡Data not provided because they were judged potentially unreliable according to National Health and Nutrition Examination Survey analytic guidelines.³² prevalence estimates had a relative standard error of $>30\%$ and the sample size was below that recommended for analyses of complex survey data, by design effect and specified proportion. The only other data excluded were for HPV types 31/33/45 from NATSAL: unweighted prevaccination prevalence: 3/85; unweighted postvaccination prevalence: 16/215; weighted prevalence ratio 3.50 (95% CI 0.97–12.67)

RR=relative risk. p values for trends were obtained by fitting a linear regression between the log RR and the rank of vaccination coverage of each study, weighted by the inverse variances of the log RR.

*Before vaccination: cumulative number of cases and person-years up to 3 years pre-vaccination, including the year of the introduction of the human papillomavirus (HPV) vaccine. †After vaccination: cumulative number of cases and person-years 1–4 years after the introduction of vaccination, depending on data available in each study. ‡Years of post-vaccination follow-up: number of years after the introduction of HPV vaccination considered in the meta-analysis (see appendix pp 10–11 for more details). §Studies were ranked qualitatively by the national or setting-specific vaccination coverage, for which we considered the number of cohorts vaccinated and vaccination coverage achieved in each cohort. However, we could not estimate the overall vaccination coverage for each study (see appendix pp 2–4 for details about the programme description, number of cohorts vaccinated, and three-dose vaccination coverage for each study).

identical time periods,^{43,48} we only included Baandrup and colleagues' study⁴³ in our main analysis (the choice of study had no effect on our results; appendix pp 12–14).

In girls 13–19 years of age, the overall prevalence of HPV types 16 and 18 decreased significantly by 64% in the post-vaccination period (RR 0.36 [95% CI 0.25–0.53]) compared with the pre-vaccination period (figure 2A), with a significant dose–response association with vaccination coverage ($p = 0.005$). The overall prevalence of HPV types 31, 33, and 45 also decreased significantly post-vaccination by 28% (RR 0.72 [95% CI 0.54–0.96]), but the reductions were not associated with vaccination coverage. The overall prevalence of HPV types 31, 33, 45, 52, and 58, and non-vaccine high-risk types (ie, all high-risk HPV types except HPV16 and HPV18) did not change significantly between the pre-vaccination and post-vaccination periods (figure 2A).

In women 20–24 years of age, the overall prevalence of HPV types 16 and 18 decreased by 31% (RR 0.69 [95% CI 0.47–1.01]) in the post-vaccination period (figure 2B). Although the overall reduction in HPV16 and HPV18 infection was not significant, it showed a dose–response association with vaccination coverage ($p = 0.01$). No significant decreases in prevalence or dose–response associations with vaccination coverage were recorded for HPV types 31, 33, and 45, or for HPV types 31, 33, 45, 52, and 58. Finally, a small—but non-significant—increase in non-vaccine high-risk HPV types occurred (RR 1.09, 95% CI 0.98–1.22), which was negatively associated with increasing vaccination coverage ($p = 0.03$).

In addition to vaccination coverage, the use of adjusted or crude RRs emerged as a substantial source of heterogeneity between studies (I^2 ranged between 50% and 75% for many endpoints; figure 3). Notably, the point estimates of adjusted RRs were lower than were the crude RRs for HPV subgroups with substantial post-vaccination reductions (ie, HPV types 16 and 18 in 20–24-year-old women; figure 3B, and HPV types 16 and 18 and types 31, 33, and 45 in 13–19 year-old girls; figure 3A), but were higher than the crude RRs for the other endpoints (figure 3).

In girls aged 15–19 years in countries using the quadrivalent vaccine, anogenital warts decreased significantly by 31% (RR 0.69 [95% CI 0.60–0.79]) in the post-vaccination period. A notable dose–response association was recorded between anogenital wart reduction and increase in population-level female vaccination coverage ($p = 0.0007$; figure 4A). In the same group, anogenital warts were reduced more substantially (by 61%) in studies with high vaccination coverage than in those with low vaccination coverage (14% reduction;

Figure 5: Subgroup analyses of the changes in anogenital wart diagnosis between the pre-vaccination and post-vaccination periods in (A) girls aged 15–19 years, (B) women aged 20–39 years, (C) boys aged 15–19 years, and (D) men aged 20–39 years

Data are for years with female-only vaccination programmes. RR=relative risk.

figure 5A). In addition to vaccination coverage, years since the start of vaccination emerged as a significant source of heterogeneity ($I^2=68\%$, $p=0.02$; figure 5A).

In countries that used the quadrivalent vaccine, non-significant decreases in anogenital warts were recorded post-vaccination in women 20–39 years of age (11%, RR 0.89 [95% CI 0.79–1.02]) and in boys 15–19 years of age (5%, 0.95 [0.84–1.08]; figure 4B, 4C). Again, these reductions showed a significant dose–response association with increased population-level female

vaccination coverage ($p=0.05$ for older women and $p=0.005$ for young men). Subgroup analyses showed that female vaccination coverage was a main source of heterogeneity (figure 5B, 5C). In countries with high female vaccination coverage, anogenital warts were reduced significantly by 32% in women aged 20–39 years (RR 0.68 [95% CI 0.51–0.89]) and by 34% in boys aged 15–19 years (0.66 [0.47–0.91]). No changes in anogenital warts were recorded in men aged 20–39 years in countries using the quadrivalent vaccine (figure 4D).

Figure 6: Changes in anogenital wart diagnosis during the first 4 years after the introduction of human papillomavirus vaccination with the quadrivalent vaccine

Results are stratified by age and female vaccination coverage: (A) Girls and women, with high female vaccination coverage ($\geq 50\%$); (B) girls and women, with low female vaccination coverage ($< 50\%$); (C) boys and men, with high female vaccination coverage ($\geq 50\%$); (D) boys and men, with low female vaccination coverage ($< 50\%$). For high coverage, the results from the following studies were combined depending on the years of follow-up available: years 1 and 2: Oliphant and Perkins (2011),³⁸ Baandrup et al (2013),⁴³ and Ali et al (2013);⁴² years 3 and 4: Ali et al (2013).⁴² For low coverage, the results from the following studies were combined depending on the years of follow-up available: year 1: Leval et al (2013),⁴¹ Kliewer et al (2012),⁴⁰ Flagg et al (2013),⁴⁵ Nsouli-Maktabi et al (2013),⁴⁷ and Mikolajczyk et al (2013);⁴⁶ years 2, 3, and 4: Leval et al (2013),⁴¹ Flagg et al (2013),⁴⁵ Nsouli-Maktabi et al (2013),⁴⁷ and Bauer et al (2013).³⁹ See appendix pp 2–4 for information about vaccination coverage in each study.

The only study that assessed population-level changes in anogenital warts following vaccination with the bivalent vaccine⁴⁴ reported a small but significant decrease in these warts in girls aged 15–19 years (figure 4A). Conversely, a small but significant increase in anogenital warts was recorded in boys aged 15–19 years (figure 4C), and no significant effect was noted in older people of either sex (figure 4B, 4D).

Figure 6 shows the changes over time in anogenital warts in studies of the quadrivalent vaccine, with the main sources of heterogeneity taken into consideration. Figure 6A clearly shows a rapid and significant decrease in anogenital warts over time in girls and women younger than 30 years of age in studies with high vaccination coverage. However, in studies with low vaccination coverage (figure 6B), the decline was recorded only in girls younger than 20 years of age, and became significant only in the third year after vaccination implementation. A rapid and significant decline in anogenital warts over time also occurred in boys and men younger than 30 years of age in studies with high female vaccination coverage (figure 6C). However, in studies with low female vaccination coverage, there was a general pattern of anogenital warts increasing over time, particularly in older men (figure 6D).

A significant decrease in high-grade precancerous cervical lesions was recorded in the only study⁴⁹ that reported these data for girls aged 15–19 years (RR 0·69, 95% CI 0·66–0·73), but no significant change was recorded in the two studies reporting data in women aged 20 years and older (appendix p 15).

Discussion

This systematic review and meta-analysis, representing more than 140 million person-years of follow-up data from nine high-income countries, reports significant population-level decreases in HPV-related outcomes up to 4 years after the implementation of HPV vaccination programmes. In countries with high vaccination coverage, HPV16 and HPV18 infection, and anogenital warts decreased by more than 60% in girls younger than 20 years of age, starting after the first year of the vaccination programmes. Furthermore, in these countries, our results suggest evidence of vaccine cross-protection and herd effects, with significant reductions in HPV31, HPV33, and HPV45 infection in girls younger than 20 years of age, and in anogenital warts in men and older women. In countries with low vaccination coverage, significant reductions were recorded for HPV16 and HPV18 infection and anogenital warts in girls younger than 20 years of age, but no significant reductions were noted for HPV31, HPV33, and HPV45 in this group, or HPV-related outcomes in boys, men, and older women (ie, no indication of cross-protection or herd effects). Our findings provide strong evidence that HPV vaccination is highly effective and can provide cross-protection outside trial settings, and reinforce the need for early vaccination

and high vaccination coverage to maximise population-level effectiveness and herd effects.

Although this meta-analysis is based on time-trend ecological studies, and therefore causality cannot be concluded, several factors strongly suggest that the reported reductions in population-level HPV-related outcomes can be attributed to HPV vaccination. These factors are: the magnitude of the effect; the dose–response association between vaccination coverage and effect; and consistency, both between the studies included in the review (despite the different methods and settings) and with results from clinical trials and mathematical modelling. First, reductions in HPV types 16 and 18, anogenital warts, and high-grade cervical lesions were large and statistically significant in the target age groups for vaccination (girls <20 years of age). Second, we found a statistically significant positive association between increases in vaccination coverage and reduction in HPV types 16 and 18 infection in girls younger than 20 years of age and anogenital warts in both women and men. Furthermore, reductions in anogenital warts increased over time since vaccination (as the number of vaccinated cohorts increased), especially in youngest age groups with highest vaccination coverage. Third, the results showed consistency between countries with similar levels of vaccination coverage. Furthermore, in the studies in which the vaccine status was available, vaccinated women had significantly lower HPV-related outcomes than did unvaccinated women in the post-vaccination era.^{32–34,37,42,53–56} Our results are also consistent with data from clinical trials that showed a high vaccine-type efficacy,^{11,12} and suggested some degree of cross-protection against HPV types 31, 33, and 45, but not against types 52 or 58.¹⁶ However, the higher bivalent cross-protective efficacy reported in a recent meta-analysis of clinical trial data¹⁶ was not shown in our population-level meta-analysis. Finally, the large herd effects reported with high vaccination coverage are consistent with predictions from dynamic models.^{20–24}

The studies included in the meta-analysis possess the strengths and weaknesses inherent in ecological studies. They provide a wealth of timely information about the effects of HPV vaccination using large study populations, but are especially vulnerable to information bias and confounding (appendix pp 5–9). However, the three most important potential sources of bias and confounding in these studies are likely to underestimate the effect of vaccination. First, because of increased awareness of anogenital warts from licensing of the HPV vaccines and the launch of the vaccination programmes, potential exists for confounding related to possible increases in health-seeking behaviours and information bias from increased diagnosis of anogenital warts over time.

Second, most studies had insufficient or no information to adequately control for sexual activity, which might have been increasing over time.^{43,57,58} These limitations might explain the slight increase in the prevalence of non-vaccine

high-risk HPV types and anogenital wart consultations in the post-vaccination period within groups with low or no vaccination coverage (eg, women older than 20 years, and men).

Third, information bias might be present as a consequence of masking by HPV type 16 and 18, especially in the pre-vaccine period.⁵⁹ That is, by preventing HPV16 and HPV18 infection, vaccination could remove the potential masking effect of these types, producing increased detection of non-vaccine types. Conversely, the main potential source of overestimation of vaccination effects is present in clinic-based studies that measure the proportion of consultations attributable to anogenital warts in sexual health clinics (appendix pp 7–8).^{38,42} Indeed, changes in the clientele of the clinics between the pre-vaccination and post-vaccination periods could overestimate the vaccination effect on anogenital warts if consultations due to other causes (eg, chlamydia consultations⁴³) became more frequent. Clinic-based studies represent two-thirds of the studies assessing the population-level effect of vaccination on anogenital warts in countries with high vaccination coverage, and could partly explain slight reductions in anogenital warts in adult men.

Fourth, the external validity of the studies was generally good (appendix pp 5–9). However, because most studies were undertaken on individuals consulting the health system, the results for the effect of HPV vaccination might not be completely generalisable to groups with lower levels of health-seeking behaviour, especially in countries in which the HPV vaccine is delivered in health-care clinics. Finally, in view of the indirect nature of our inferences, our analysis might not have had adequate sensitivity to detect small post-vaccination effects (eg, type-replacement, or herd effects and cross-protection when vaccination coverage is low).

Our results should be interpreted cautiously because they represent only the short-term population-level effects of HPV vaccination programmes. First, the cohorts of vaccinated girls have not yet reached the ages with highest incidence rates of HPV infection, anogenital warts, and cervical lesions (ie, between 20 and 35 years of age). Therefore, the direct and herd effects are expected to continue to increase over time as overall population-level vaccination coverage increases.

Second, the existing evidence is insufficient to draw conclusions about the existence of net type-replacement (eg, no significant increase in the prevalence of high-risk non-vaccine HPV types in groups with the highest vaccination coverage), which could be because no type-replacement is occurring, or partly a consequence of the short follow-up time or dilution of type-specific changes by grouping HPV types.

Third, the time horizon was too short to examine waning of vaccine efficacy. However, randomised controlled trials have shown no signs of waning vaccine efficacy after 9·5 years of follow-up.⁶⁰

Fourth, in view of the long lag time between infection and cancer, no direct evidence of the effect of vaccination on HPV-related cancers is currently available. However, since HPV infection is the cause—and high-grade precancerous cervical lesions the precursors—of cervical cancer, these intermediate outcomes have been judged acceptable proxies for efficacy against cervical cancer by regulatory bodies worldwide.^{61–64} Nevertheless, one should be careful in using reductions in precancerous cervical lesions from screening databases as proxies for cervical cancer because they might represent changes in screening recommendations and participation, and they are not HPV type-specific. Additionally, surveillance studies based on cervical screening registries could overestimate the population-level effect of HPV vaccination, if vaccine uptake is higher in women who undergo screening.^{65–68}

Finally, as previously shown, trends in HPV types 6 or 11-related disease (eg, anogenital warts) are a poor proxy of change in HPV types 16 and 18 and related diseases (eg, cervical cancer).⁶⁹ This is because HPV6 and HPV11 will be easier to eliminate and control through vaccination than HPV16 and HPV18 because of their shorter durations of infectiousness and lower transmissibility.

Our overall findings are likely generalisable to high-income countries, since most of the heterogeneity between countries disappeared once results were stratified by vaccination coverage and age, and given similarities in sexual behaviour,⁵⁸ HPV type distribution,^{70,71} age profile of HPV prevalence,⁷² and cervical cancer incidence between high income countries.⁷³ However, precise estimates of population-level effect will vary between countries according to their programmatic specificities, such as the characteristics of catch-up campaigns.

Our results should be extrapolated to low-income and middle-income countries with caution because all studies in the meta-analysis were from high-income countries and substantial differences exist between these countries and low-income and middle-income countries in sexual behaviour,⁵⁸ HPV epidemiology,^{72,73} and potential cofactors of HPV infection and disease, such as high HIV prevalence.⁷⁴ However, no evidence exists to suggest that vaccine efficacy would be lower in low-income and middle-income countries, especially because the vaccine has been shown safe and immunogenic in women with HIV infection.⁷⁵ On the other hand, herd effects could differ in low-income and middle-income countries with very different population-level sexual behaviour (eg, increased mixing between older men and younger women, and more concurrency in partnerships). Even in the unlikely scenario that there would be no herd effects in such countries, a recent global modelling study (PRIME)¹⁹ has shown that HPV vaccination would be highly cost effective, in view of the very high cervical cancer incidence and mortality in these countries,

This first meta-analysis of the population-level effect of HPV vaccination programmes shows compelling evidence of a strong and statistically significant dose-response

association between HPV vaccination coverage and reductions in HPV16 and HPV18 infection and anogenital warts in cohorts of girls and women targeted for vaccination. Additionally, our study provides the first evidence of a dose–response association between female vaccination coverage and reduction of anogenital warts in older women and men.

Our results have important policy implications. The sharpest declines in HPV-related outcomes in both male and female participants were recorded in countries with school-based vaccine delivery (eg, the UK, Australia, and New Zealand), which suggests that this strategy helps faster rollout and higher vaccination coverage than non-school-based vaccine programmes. Our study also shows population-level data supporting clinical trial evidence of HPV vaccine cross-protection against HPV types 31, 33, and 45, although no dose–response with vaccination coverage was recorded.

In conclusion, the results of this study are very promising for the long-term population-level effect of HPV vaccination programmes on cervical cancer and other HPV-related diseases. However, we must continue to monitor and evaluate HPV vaccination programmes to confirm these results, and we need to remain vigilant for evidence of potential waning efficacy, type-replacement, or lower vaccination coverage in groups at greater risk of HPV-related cancers.

Contributors

MD, MB, and M-CB conceived the study. MD and EB did the literature search and did the analysis. MB, M-CB, AM, PL-M, and JB participated in the analysis. MD and MB codrafted the first version of the report. DM independently assessed eligibility of studies on human papillomavirus infection. All other authors (HA, LB, HB, SB, JMLB, TC, BD, CKF, EWF, AMJ, JAK, KK, SKK, EVK, LM, DM, LN, JO, KGP, KS, PS, SNT, and CT) provided data, after having done supplementary analysis for the purposes of this meta-analysis. All authors interpreted the results and critically revised the report for scientific content. All authors approved the final version of the report.

Declaration of interests

In the past 3 years, MB reports unrestricted grants from Merck (for herpes zoster research—none are ongoing). MD has done consulting work for GlaxoSmithKline (herpes zoster vaccine). HA has received a grant from bioCSL for the Australian genital warts surveillance network. SB, DM, and KS have received grants from GlaxoSmithKline for human papillomavirus testing of some samples (study number EPI-HPV-109903). JMLB has received grants from bioCSL and Merck. BD has received grants from bioCSL and speaker fees from Merck and Sanofi Pasteur MSD. CKF owns shares in CSL Biotherapies who have licensed the Gardasil vaccine to Merck, and has received travel reimbursement and speaker fees from Merck. AMJ has been a Governor of the Wellcome Trust since 2011. JAK has received a grant from Merck. SKK has received grants from Merck and is a member of the Scientific Advisory Board of Merck and an expert lecturer for Sanofi Pasteur MSD. EVK has received grants from Merck and GlaxoSmithKline and personal fees from Merck. LN has received consulting fees from Merck. SNT has received grants from bioCSL. EB, M-CB, LB, HB, JB, TC, EWF, KK, PL-M, LM, AM, JO, KGP, PS, and CT declare no competing interests.

Acknowledgments

The findings and conclusions in this report are those of the authors and do not necessarily represent the official position of the Centers for Disease Control and Prevention. This work was supported by the Canada Research Chairs programme (support for MB) and an operating grant from the Canadian Institutes of Health Research (grant no. MOP-119427). The

authors would also like to thank Caty Blanchette for doing statistical analysis, Michael Malloy for supplementary analysis of the Australian data, Rebecca Howell-Jones who did the original analyses of decreases in genital warts in England, and Kavita Panwar who undertook the human papillomavirus testing for the report by Mesher and colleagues.
